

Batch Name : OM32

Module Name : Data Structures

=====

DS DAY-01:

+ Introduction to an DS:

- if we want to store marks of 100 students

int m1, m2, m3, m4, m5,, m100; //sizeof(int)*100 =
400 bytes

if we want to sort marks of 100 students =>

int marks[100]; //sizeof(int)*100 = 400 bytes

+ "array" => an array is a basic/linear data structure which is a collection of logically related similar type of elements gets stored into the memory at contiguous locations.

int arr[5];

arr : int []
arr[0] : int
arr[1] : int
.
.
.

primitive data types: char, int, float, double, void

non-primitive data types: array, structure, pointer, enum

- we want to store info of 100 students

rollno : int
name: char []/string
marks : float

+ "structure" => it is a basic/linear data structure, which is a collection of logically related similar and dissimilar type of data elements gets stored into the memory collectively as a single record/entity.

```
struct student
{
    int rollno;
    char name[ 32 ];
    float marks;
};
```

C => Array

C++ => Array

Java=> Array

Python => Array

=> data structures is a programming concept

=> to learn data structures is not learn any programming language, it is nothing but to learn an algorithm, data structure algorithms can be implemented in any programming language.

=> in this course we will use C programming language.

Prerequisite: C

Q. What is a Program?

Q. What is an algorithm?

Q. What is a Pseudocode?

- to traverse an array => to visit each array element sequentially from first element max till last element.

+ "algorithm" => to do sum of array elements => any human user

step-1: initially take sum var as 0

step-2: traverse an array and add each array element sequentially into the sum variable
step-3: return final sum

+ "pseudocode" => to do sum of array elements => programmer user

Algorithm ArraySum(A, n){//whereas A is an array of size "n"

```
    sum = 0;
    for( index = 1 ; index <= n ; index++ ){
        sum += A[ index ];
    }
```

```
    return sum;
```

```
}
```

- pseudocode is a special form of an algorithm in which finite set of instructions can be written in human understandable language with some programming constraints.

+ "program" => to do sum of array elements => machine

```
int array_sum(int arr[], int size){
```

```
    int sum = 0;
```

```
    int index;
```

```
    for( index = 0 ; index < size ; index++ )
```

```
        sum += arr[ index ];
```

```
    return sum;
```

```
}
```

flowchart => it is a digramatic representation of an algorithm.

=> an algorithm is a solution of a given problem.

=> an algorithm = solution

- "one problem may has many solutions", and in this case there is a need to decide an efficient solution.

e.g. searching => to find/search a key element in a given collection/list of data elements.

1. linear search
2. binary search

e.g. sorting => to arrange data elements in a collection/list of elements either in an ascending order or in a descending order.

1. selection sort
 2. bubble sort
 3. insertion sort
 4. quick sort
 5. merge sort
- etc...

- to decide efficiency of an algorithms, we need to do their analysis

- there are two measures of an analysis of an algorithms:

1. time complexity
2. space complexity

linear search =>

step-1: accept key from user

step-2:

```
for( index = 1 ; index <= size ; index++ ){  
    //if matches with any array element  
    if( key == arr[ index ] )  
        return true;  
}
```

```
//if key do not matches with any array element  
return false;
```

if key is found in an array at very first pos

if size of an array = 10 => no. of comparisons = 1

if size of an array = 20 => no. of comparisons = 1

if size of an array = 50 => no. of comparisons = 1

.

.
if size of an array = $n \Rightarrow$ no. of comparisons = 1

for any input size array no. of comparisons in this case
= 1 \Rightarrow best case
running time of an algo in best case = $O(1)$.

+ worst case:

if either key is found in an array at last pos or key do
not found

if size of an array = 10 \Rightarrow no. of comparisons = 10

if size of an array = 20 \Rightarrow no. of comparisons = 20

if size of an array = 50 \Rightarrow no. of comparisons = 50

.
.

if size of an array = $n \Rightarrow$ no. of comparisons = n

no. of comparisons = depends on size of an array
for any input size array no. of comparisons in this case
= $n \Rightarrow$ worst case
running time of an algo in worst case = $O(n)$.

+ asymptotic rules: (discrete maths)

"rule-1" : if running time of an algo is having any
additive/subtractive/divisive/multiplicative constant
then it can be neglected.

e.g.

$O(n+3) \Rightarrow O(n)$

$O(n-5) \Rightarrow O(n)$

$O(2*n) \Rightarrow O(n)$

$O(n/2) \Rightarrow O(n)$

typedef unsigned long int size_t;

2. binary search:

by means of calculating mid pos big size array gets divided logically into two subarray's => left subarray & right sub array
left subarray => left to mid-1
right subarray => mid+1 to right

for left subarray => value of left remains same, right = mid-1
for right subarray => value of right remains same, left = mid+1

if(left == right) => subarray contains only 1 ele and it is valid

if(left <= right) => subarray is valid
in other words :

if(left > right) => subarray is invalid

DS DAY-02:

if size of an array = 1000

iteration-1: search space = n => 1000

[0 999]
[0.... 499] [501 999]

iteration-2: search space = $n/2 = 500$

[0.... 499]
[0...249] [251499]

iteration-3: search space = $n/2 / 2 => n / 4 = 250$

[0...124] [126 ...249]

iteration-4: search space = $n/4 / 2 => n / 8 = 125$

after every iteration search space is getting reduced by half

$n => n/2 => n/4 => n/8 \dots$

$n => n / 2^0$

$n/2 => n / 2^1$

$n/4 => n / 2^2$

$n/8 => n / 2^3$

- search space is getting reduced exponentially

- binary search is also called as logarithmic search, and hence we get time complexity of binary search in terms of log.

Rule => if any algo follows divide-and-conquer approach then we get time complexity of that algo in terms of log.

Best Case => if key is found at root position in only 1 comparison => $O(1)$ => $\Omega(1)$.

Worst Case => if either key is found at leaf position or key is not found => $O(\log n)$ => $O(\log n)$

Average case => if key is found at non-leaf position
=> $O(\log n)$ => $\Theta(\log n)$.

+ Sorting Algorithms:

1. Selection Sort:

iteration-1: no. Of comparisons = $n-1$

iteration-2: no. Of comparisons = $n-2$

iteration-3: no. Of comparisons = $n-3$

.

.

.

iteration-($n-1$): no. Of comparisons = 1

total no. of comparisons = $(n-1)+(n-2)+(n-3)+\dots+1$

arithmetic progression formula:

=> $n(n-1) / 2$

=> $(n^2 - n) / 2$

=> $O((n^2 - n) / 2)$

=> $O(n^2 - n)$...by neglecting divisive constant

=> $O(n^2)$ by using rule of polynomial only leading term is considered

rule => if running time of an algo is having a polynomial, then in its time complexity of leading term will be considered.

e.g.

$O(n^3 + n^2 + n - 3)$ => $O(n^3)$

$O(n^2 + 5)$ => $O(n^2)$

2. Bubble Sort:

iteration-1: no. Of comparisons = $n-1$

iteration-2: no. Of comparisons = $n-2$

iteration-3: no. Of comparisons = $n-3$

.

.

.

iteration- $(n-1)$: no. Of comparisons = 1

total no. of comparisons = $(n-1)+(n-2)+(n-3)+\dots+1$

by arithmetic progression formula:

$\Rightarrow n(n-1) / 2$

$\Rightarrow (n^2 - n) / 2$

$\Rightarrow O((n^2 - n) / 2)$

$\Rightarrow O(n^2 - n)$...by neglecting divisive constant

$\Rightarrow O(n^2)$ by using rule of polynomial only leading term is considered

for itr=0 \Rightarrow pos=0,1,2,3,4

for itr=1 \Rightarrow pos=0,1,2,3

for itr=2 \Rightarrow pos=0,1,2

for itr=3 \Rightarrow pos=0,1

.

.

.

for(pos=0 ; pos < $6-1-itr$; pos++)

10 20 30 40 50 60

iteration-1:

10 20 30 40 50 60

10 20 30 40 50 60

10 20 30 40 50 60

10 20 30 40 50 60

10 20 30 40 50 60

- if all pairs in an array are already inorder => there is no need of swapping => array is already sorted

- by basic algo/by design bubble is not efficient for already sorted input array, but it can be implemented efficiently by using logic of flag.

- best case occurs in bubble if array ele's are already sorted.

In this case only 1 iteration takes place and no. Of comparisons = $n-1$

$T(n) = O(n-1)$

$T(n) = O(n) \Rightarrow \Omega(1)$.

DS DAY-03:

3. Insertion Sort:

Best Case - if array is already sorted

Input Array : 10 20 30 40 50 60

iteration-1:

10 20 30 40 50 60

10 20 30 40 50 60

no. of comparisons = 1

iteration-2:

10 20 30 40 50 60

10 20 30 40 50 60

no. of comparisons = 1

iteration-3:

10 20 30 40 50 60

10 20 30 40 50 60

no. of comparisons = 1

iteration-4:

10 20 30 40 50 60

10 20 30 40 50 60

no. of comparisons = 1

iteration-5:

10 20 30 40 50 60

10 20 30 40 50 60

no. of comparisons = 1

- in best case in each iteration only 1 comparison takes place and in max (n-1) no. Of iterations array elements gets arranged in a sorted manner.

Total no. of comparisons = $1 \times (n-1) = n-1$

$T(n) = O(n-1) = O(n) = \Omega(n)$.

4. Merge Sort:

by means of calculating mid pos big size array gets divided logically into two subarray's => left subarray and right subarray

left subarray => left to mid

right subarray => mid+1 to right

for left subarray => value of left remains same, and
right = mid

for right subarray => value of right remains same, and
left = mid+1

5. Quick Sort:

- we can apply partitioning on any partition only if size of an array/partition is greater than 1 i.e. only if left > right.

if(left == right) => partition contains only 1

if(left < right) => partition contains more 1 ele's

if(left > right) => partition is invalid

worst case occurs in quick sort if array is already sorted or array elements are exists exactly in a reverse order.

Pass-1:

```
[ 10 20 30 40 50 60 ]  
[ LP ] 10 [ 20 30 40 50 60 ]
```

Pass-2:

```
[ 20 30 40 50 60 ]  
[ LP ] 20 [ 30 40 50 60 ]
```

Pass-3:

```
[ 30 40 50 60 ]  
[ LP ] 30 [ 40 50 60 ]
```

Pass-4:

```
[ 40 50 60 ]  
[ LP ] 40 [ 50 60 ]
```

Pass-5:

```
[ 50 60 ]  
[ LP ] 50 [ 60 ]
```

DS DAY-04:

```
int arr[ 100 ];
```

addition operation on an array is not efficient as takes $O(n)$ time

Why Linked List ?

Linked List must be dynamic and addition & deletion operations should perform on it efficiently i.e. expected time is $\Rightarrow O(1)$.

What is a Linked List ?

Singly Linear Linked List:

```
if( head == NULL )  $\Rightarrow$  list is empty
```

Q. What is NULL ?

- NULL is a predefined macro whose value is 0 which is typecasted into a void *

```
#define NULL ((void *)0)
```

```
data : int  
next : *type
```

```
struct node  
{  
    int data;//4 bytes  
    struct node *next;//4 bytes  
};
```

```
sizeof(struct node) = 8 bytes  
sizeof(struct node *) = 4 bytes
```

```
to store an addr of int type var => int *
```

```
to store an addr of char type of var => char *
```

```
to store an addr of float type var => float *
```

```
.  
.
```

```
to store an addr of struct node type var => struct node *
```

```
to store an addr of type var => type *
```

```
sizeof(char) = 1 byte  
sizeof(int) = 4 bytes  
sizeof(float) = 4 bytes  
sizeof(double) = 8 bytes
```

```
sizeof(char *) = 4 bytes  
sizeof(int *) = 4 bytes  
sizeof(float *) = 4 bytes  
sizeof(double *) = 4 bytes  
sizeof(sturct node *) = 4 bytes
```

```
sizeof(type *) = 4 bytes (on 32-bit compiler)
```

- We can perform basic 2 operations on Linked List:

1. addition : to add node into the linked list

- we can add node into the linked list by 3 ways

- i. add node into the linked list at last position
- ii. add node into the linked list at first position
- iii. add node into the linked list at specific (in between) position.

2. deletion : to delete node from linked list

- we can delete node from the linked list by 3 ways

- i. delete node from the linked list which is at first position
- ii. delete node from the linked list which is at last position
- iii. delete node from the linked list which is at specific (in between) position

i. add node into the linked list at last position:

- we can add as many as we want number of nodes into the slll at last position in **$O(n)$** time.

Best Case : $\Omega(1)$
Worst Case : $O(n)$
Average Case : $\Theta(n)$

ii. add node into the linked list at first position:

- we can add as many as we want number of nodes into the slll at first position in **$O(1)$** time.

Best Case : $\Omega(1)$
Worst Case : $O(1)$
Average Case : $\Theta(1)$

iii. add node into the linked list at specific (in between) position:

- we can add as many as we want number of nodes into the slll at specific position in **$O(n)$** time.

Best Case : $\Omega(1)$ - if pos = 1

Worst Case : $O(n)$ - if $pos = count_nodes() + 1$
Average Case : $\Theta(n)$ - if pos is in between pos

Procedure => Function

C Programming Language => **Procedure Oriented Programming Language** => Logic of a program gets divided into functions

C++ Programming Language => Object Oriented Programming Language => Logic of a program gets divided into an objects.

=> to traverse a linked list => to visit each node in a linked list sequentially from first node max till last node.

- we can start traversal of a linked list from first node
- we get an addr of first node always from head

Rule in a Linked List Programming => **make before break**
i.e. always creates new links first (links associated with newly created node) and then only break old links.

DS DAY-05:

2. deletion : to delete node from linked list

- we can delete node from the linked list by 3 ways

i. delete node from the linked list which is at first position: $O(1)$

Best Case : $\Omega(1)$
Worst Case : $O(1)$
Average Case : $\Theta(1)$

ii. delete node from the linked list which is at last position : $O(n)$

Best Case : $\Omega(1)$ - if list contains only 1 node
Worst Case : $O(n)$
Average Case : $\Theta(n)$

iii. delete node from the linked list which is at specific position : $O(n)$

Best Case : $\Omega(1)$ - if pos = 1
Worst Case : $O(n)$
Average Case : $\Theta(n)$

SCLL:

if(head == NULL) => list is empty
if(head != NULL) => list is not empty

if(head == head->next) => list contains only one node
otherwise list contains more than one nodes.

- all operations/algos we applied on SLLL, we can apply on SCLL as well exactly as it is except in SCLL we need to maintained/take care about next part of last node always.

DLLL:

```
struct node
{
    struct node *prev;
    type data; //any primitive / non-primitive type
    struct node *next;
};
```

sizeof(struct node) = 12 bytes on 32-bit compiler

if(head == NULL) => list is empty
if(head != NULL) => list is not empty

if(head->next == NULL) => list contains only one node
otherwise list contains more than one nodes.

- all operations/algos we applied on SLLL, we can apply on DLLL as well exactly as it is except in DLLL we need maintain forward link as well as backward link of each node i.e. next part as well as prev part of each node.

DCLL:

```
if( head == NULL ) => list is empty
if( head != NULL ) => list is not empty
```

```
if( head == head->next ) => list contains only one node
otherwise list contains more than one nodes.
```

- all operations/algo's we applied on SLLL, we can apply on DCLL as well exactly as it is except in DCLL we need maintain forward link as well as backward link of each node i.e. next part as well as prev part of each node and we need maintains prev part of first node and next part of last node.

Optional Home Work => Implement SCLL, DLLL & DCLL addition & deletion operations.

DS DAY-06:

+ Stack:

- We can perform basic 3 operations onto the Stack in $O(1)$ time.

1. Push : to insert/add an element onto the stack from top end.

2. Pop : to delete/remove an element from the stack which is at top end.

3. Peek : to get/read the value of an element which is at top end (without Push or Pop).

- Stack can be implemented by 2 ways:

1. Static Stack (by using an array)

2. Dynamic Stack (by using linked list)

1. Static Stack (by using an array):

```
struct stack
```

```
{  
    int arr[ 5 ];  
    int top;  
};
```

arr : int [] - non-primitive data type

top : int - primitive data type

1. Push : to insert/add an element onto the stack from top end.

step-1: check stack is not full (if stack is not full then only element can be pushed onto it from top end).

step-2: increment the value of top by 1

step-3: insert an element onto the stack at top end

2. Pop : to delete/remove an element from the stack which is at top end.

step-1: check stack is not empty (if stack is not empty then only element can be deleted from it which is at top end).

step-2: decrement the value of top by 1

[by means of decrementing value of top by 1 we are achieving deletion of an element from the stack].

3. Peek : to get/read the value of an element which is at top end (without Push or Pop).

step-1: check stack is not empty (if stack is not empty then only value of an element which is at top end can be peeked).

step-2: return the value of topmost element (without incrementing/decrementing value of top).

- if you want to display the print array from 0 to top.
- as we do not perform traversal operation on stack so display stack is invalid operation.

- Stack can be implement dynamically using linked list (dcll) .

Stack => Last In First Out List

- Linked List => Dynamic Stack =>
- List is Empty => Stack Empty
- Linked List is dynamic data structure so there no Stack Full condition for dynamic stack.
- Push => add_last()
- Pop => delete_last()
- Peek => get value of data part of a last node

head =>

OR

- Push => add_first()
- Pop => delete_first()
- Peek => get value of data part of a first node

Q. What is an expression ?

- an expression is a combination of an operands and an operators.
- there are 3 types of expressions:
 1. infix expression : a+b
 2. prefix expression : +ab
 3. postfix expression : ab+

1. infix to postfix (parenthesized as well as non-parenthesized) .

2. infix to prefix
3. prefix to postfix
4. postfix evaluation

DS DAY-07:

+ **Queue** : it is a basic/linear data structure, which is a collection of logically related similar type of data elements in which elements can be added into it from one end referred as rear end, whereas elements can be deleted from it from another end referred as front end.

On queue we can perform 2 basic operations in $O(1)$ time:

1. **enqueue** : to insert an element into the queue from rear end.
2. **dequeue** : to delete an element from the queue which is at front end.

There are 4 types of queue:

1. **linear queue (fifo)**
2. **circular queue (fifo)**
3. **priority queue** : it is a type of queue in which elements can be added into it randomly (i.e. without checking priority) from rear end, whereas element which is having highest priority can only be deleted first.
4. **double ended queue (deque)**: it is a type of queue in which elements can be added as well deleted from both the ends.
 - there are 2 subtypes of deque:
 1. **input restricted deque** : it is a type of deque in which elements can be added into it only from one end, whereas elements can be deleted from both the ends.
 2. **output restricted deque** : it is a type of deque in which elements can be added from both the ends, whereas elements can be deleted only from one end.

- there are two ways which linear queue can be implemented

1. static queue (by using an array)
2. dynamic queue (by using linked list)

1. static queue (by using an array):

```
struct queue
{
    int arr[ 5 ];
    int rear;
    int front;
}
```

```
arr      : int []
rear     : int
front    : int
```

1. enqueue : to insert an element into the queue from rear end.

step-1: check queue is not full (if queue is not full then only element can be inserted into it from rear end).

step-2: increment the value of rear by 1

step-3: insert element into the queue from rear end

step-4: if(front == -1)
front = 0

2. dequeue : to delete an element from the queue which is at front end.

step-1: check queue is not empty (if queue is not empty then only element can be deleted from it which is at front end).

step-2: increment the value of front by 1.

[by means of incrementing value of front by 1 we are achieving deletion of an element from the queue].

Circular Queue:

```
rear = 4, front = 0
rear = 0, front = 1
rear = 1, front = 2
rear = 2, front = 3
rear = 3, front = 4
```

if front is at next pos of rear => cir queue is full

```
if( front == (rear + 1) % SIZE )
```

```
for rear = 0, front = 1 => front is at next pos rear
front == (rear + 1) % SIZE
```

```
=> 1 == (0+1)%5
```

```
=> 1 == 1 % 5
```

```
=> 1 == 1 ==> LHS == RHS ==> Cir Q is full
```

```
for rear = 1, front = 2 => front is at next pos rear
front == (rear + 1) % SIZE
```

```
=> 2 == (1+1)%5
```

```
=> 2 == 2 % 5
```

```
=> 2 == 2 ==> LHS == RHS ==> Cir Q is full
```

```
for rear = 2, front = 3 => front is at next pos rear
front == (rear + 1) % SIZE
```

```
=> 3 == (2+1)%5
```

```
=> 3 == 3 % 5
```

```
=> 3 == 3 ==> LHS == RHS ==> Cir Q is full
```

```
for rear = 3, front = 4 => front is at next pos rear
front == (rear + 1) % SIZE
```

```
=> 4 == (3+1)%5
```

```
=> 4 == 4 % 5
```

```
=> 4 == 4 ==> LHS == RHS ==> Cir Q is full
```

```
for rear = 4, front = 0 => front is at next pos rear
front == (rear + 1) % SIZE
```

```
=> 0 == (4+1)%5
```

```
=> 0 == 5 % 5
```

```
=> 0 == 0 ==> LHS == RHS ==> Cir Q is full
```

increment the value of rear by 1
`rear++; => rear = rear + 1;`

increment the value of rear by 1
`rear = (rear + 1) % SIZE;`

`if rear = 0`
`=> rear = (rear + 1) % SIZE`
`=> rear = (0+1)%5 = 1%5 = 1`

`if rear = 1`
`=> rear = (rear + 1) % SIZE`
`=> rear = (1+1)%5 = 2%5 = 2`

`if rear = 2`
`=> rear = (rear + 1) % SIZE`
`=> rear = (2+1)%5 = 3%5 = 3`

`if rear = 3`
`=> rear = (rear + 1) % SIZE`
`=> rear = (3+1)%5 = 4%5 = 4`

`if rear = 4`
`=> rear = (rear + 1) % SIZE`
`=> rear = (4+1)%5 = 5%5 = 0`

DS DAY-08:

- dynamic queue (fifo) can be implemented by using linked list:

```
enqueue : add_last()
dequeue : delete_first()
```

head -> 44

OR

```
enqueue : add_first()
dequeue : delete_last()
```

dynamic queue is empty => if list is empty
there is no dynamic queue full condition

- priority queue can be implemented by using linked list (slll).

```
struct node
{
    int data;
    int priority_value;
    struct node *next;
};
```

```
Head -> | 10 : 3 : 2000 | -> | 45 : 2 : 3000 | ->
| 50 : 4 : 4000 | -> | 5 : 1 : NULL | -> NULL
```

```
enqueue -> add_first()
dequeue -> search_and_delete() => there is need to find
such a node which is having min priority value i.e.
having highest priority and then it can be deleted.
```

- priority queue can also implemented by using binary heap (it is a type of tree).

- double ended queue (deque) can be implemented by using dcll

- we can perform basic 4 operations on deque:

1. `push_back()` : `add_last()`
2. `push_front()` : `add_first()`
3. `pop_back()` : `delete_last()`
4. `pop_front()` : `delete_first()`

+ linear / basic data structures:

- array : static
- structure
- linked list (dcll) : dynamic
- stack (lifo)
- queue (fifo), priority queue, deque

+ non-linear / advanced data structures:

- tree
- graph
- hash table

+ **tree** : it is a non-linear / advanced data structure, which is collection of logically related finite no. Of data elements in which there is a first specially designated element referred as a root element, and remaining elements are connected to the root element in a hierarchical manner follows parent-child relationship.

+ **tree terminologies**:

root node

parent node/father

child node/son

siblings => child nodes of same parent are called as siblings.

grand parent/grand father

grand child/grand son

ancestors: all the nodes which are in the path from root node to that node are called as its ancestors.

- root node is an ancestor of all the nodes

descendants: all the nodes which can be accessible from that node (in a downward dir) are called as its descendants.

- all the nodes are descendent of root node.
- degree of a node = no. of child node/s having that node
- **leaf node / terminal node / external node** => node having degree 0 or node which is not having any no. of child node.
- **non-leaf node / non-terminal node / internal node** => node having non-zero degree or node which is having any no. of child node.
- level of a node = level of its parent node + 1
- level of root node = 0 OR 1
- depth of a tree = max level of any node in a given tree
- as tree is a **dynamic** in nature, **it can grow upto any level** and **any node can have any no. of child nodes**, hence operations like addition, deletion, searching etc... becomes **inefficient** on it, and to achieve operations efficiently on it certain restrictions can be applied on it, hence there are diff types of tree:
 - **binary tree** => it is a type of tree in which each node can have max 2 no. of child nodes i.e. each node can have either 0 OR 1 OR 2 no. of child nodes.
 - OR it is a type of tree in which degree of each node is either 0 OR 1 OR 2.

set = zero no. of elements => empty set/null set
 set = only 1 no. of element => singleton set
 set = more than 1 no. elements

- further restrictions can be applied on binary tree to achieve operations (mainly addition, deletion & searching) efficiently i.e. $O(\log n)$ time, binary search tree has been designed.

	Addition	Deletion	Searching
Array	$O(n)$	$O(n)$	$O(\log n)$
Linked List	$O(1)$	$O(1)$	$O(n)$

Binary Search Tree has been designed basically to achieve operations efficiently i.e. $O(\log n)$ time.

- **Binary Search Tree** : it is a **binary tree** in which **left child is always smaller than its parent** and **right child is always greater than or equal to its parent**.

- tree traversal => to visit each node at max once
- in tree data structure traversal always starts from root node.

- there are 2 basic tree traversal methods:

1. bfs (breadth first search) traversal :

- it is also called as **level-wise traversal**, in which traversal starts from root node and all nodes in a tree gets visited level wise from left to right.

2. dfs (depth first search) traversal :

further there are 3 different ways of traversal:

1. Preorder (V L R)

2. Inorder (L V R)

3. Postorder (L R V)

L - Left Subtree

R - Right Subtree

V - Visit Node (Root Node of Subtree)

1. Preorder (V L R) :

- traversal always starts from root node, we can visit cur node (i.e. root node of cur subtree), then we can visit its left subtree and then only we can visit its right subtree.

- we can visit right child / right subtree of any node only either after visiting its whole left subtree of its left subtree is empty.

- in preorder traversal root node always gets visited at first, this property remains true recursively for each subtree.

2. Inorder (L V R) :

- traversal always starts from root node

- we can visit any node only after its whole left subtree is either already visited or its left subtree is empty, and then only we can go to visit its right subtree.

- in this traversal all the node gets always visited in an ascending order sorted manner.

3. Postorder (L R V) :

- traversal always starts from root node
- we can visit any node only after visiting its left subtree as well as right subtree or they are empty.
- in postorder traversal root node always gets visited at last, this property remains true recursively for each subtree.

Hint Exam:

inorder & postorder => preorder

inorder & preorder => postorder

draw a diagram of bst from given preorder / postorder and then we can easily find its equivalent postorder/ preorder

height of a node = $\max(\text{height of its left subtree}, \text{height of right subtree}) + 1$.

height of a tree = max height of any node in a given tree

height of an empty tree = -1

- max height of bst = $O(n)$, whereas n = no. Of elements in it.

- min height of bst = $O(\log n)$, whereas n = no. of elements in it.

- bst with min height for given input size is also called as **balanced bst** => in balanced bst addition, deletion & searching operations can be performed in $O(\log n)$ time.

- bst with max height for given input size is called as **imbalanced bst** => operations like addition, deletion and searching cannot be performed in $O(\log n)$ time.

$O(n-1) \Rightarrow O(n)$

bst in which, while adding and deleting element into/from it its gets checked whether bst remains balanced or not, such bst is referred as self balanced bst and as this concept was designed by 2 mathematicians named as **adelson velsinki** and **lendis**, **self balanced bst is also called as avl tree.**
